A DRS CONSISTS OF AUTONOMOUS COMPONENTS

- A component is a hardware software unit of specified functionality and performance
- Components communicate by the exchange of RT messages only
- A component is a unit of information hiding and intelligent under fault conditions
- At the reintegration point components should contain minimal internal state
- Components should support reasonable abstractions for fault tolerance
 e.g. failsilent.

TU Wien	
Global ver:	sus Local Properties
Global pro	perties:

- * Meaning of a message
- * Function of a component
- * Timing between messages

Local properties:

- * Representation of information
- * Timing within a component
- * Timing between an interface component and the associated environment

At the architectural level, only the global properties have to be considered.

Global

Response time RT:

The maximum tolerated interval between stimulus and response of a transaction

Period P

The minimum interval between two transaction instances

Peak load:

All hard real time transactions occur with their (minimum) period P

Maxt

Maximum execution time of a transaction (on each node)

Transaction classes:

Emergency Transactions immediate service

Hard Real Time Transactions guaranteed service

Soft Real Time Transactions Best effort service

Stimulus:

External Transactions external stimulus

Internal Transactions internal stimulus

TU Wien		desev
Performan	ce evaluation of DRS:	
* Peak loa	d is a 'rare event'	
* The maxi times are	mum, not the mean respon of interest.	ıse
* Peak load catastrop a ligthnin	d is highly correlated by a ohic external event e.g. by ng stroke	
Therefore:		
* It is diffic based on	ult to follow arguments 'stochastics'	
* Design m mechanis	ust be based on determinis	stic

TU Wien

Time rigid scheduling

Assumptions: Global time base (<100 usec) available TDMA Protocol on LAN

Scheduling:

A task is started at a predetermined absolute global point in time modulo the known cycle time P

Before system initialization these time rigid schedules are calculated for all hard real time tasks

Simplification Cycle durations 2**n of basic slot times

-

Direct Transaction Delay The delay of a transaction provided that this transaction has immediate access to all required resources

Indirect Transaction Delay The delay of a transaction caused by resource coflicts (buffer, Media Access etc.)

Total delay Direct plus Indirect delay

Design goal:

Minimize indirect delay of hard real time transactions.

DISCUSSION

Rapporteur: Rogério de Lemos

Amer Saeed

Professor Ercoli asked Professor Kopetz what was his definition for a safe state, and how it could be checked whether the system was in a safe state or not. Professor Kopetz answered that a safe state is always defined in the context of a particular application, and a safe state cannot have an abstract definition without looking at the requirements of the application. Also Professor Kopetz said that it was possible to consider a situation where a safe state could be considered as a bad state, but normally this generalization did not make a big difference.

Professor Turski questioned if it was possible to design systems that could respond in real-time peak load, in accordance with the definition, by the occurrence of two lighting striking in the power net. Professor Kopetz answered that the specification of peak load must be part of the requirements specification. It was always difficult to prove real world properties, we could only prove in a mathematical system by setting them out as mathematical problems.

Based on Professor Kopetz answer Professor Turski continued exposing his thoughts stating that there are unpredictable things and the rest is predictable by definition, so for predictable things there are very well designed tools without all the variables that consider time, and the rest was unpredictable anyhow. He continued stating that if the time splitting will have to continue undefinedly there were always subunits of time that events could happen and become unobservable. In his view, there are things which we are unable to cope with and the rest is just relations of objects where time has no importance. At this point Professor Anderson asked whether Professor Turski was presuming that system design was then trivial. Replying to Professor Turski's arguments, Professor Kopetz said there were always certain assumptions which a designer must make and which are related, for example to fault hypothesis - what are the faults which can be tolerated by the system, and will "real" real life system exhibit only these properties which the system can tolerate. There are delicate assumptions that must be made at the specification of the requirements and a similar set of assumptions which must be made in relation to design properties of the system: the peak load that is to be handled and considered, and the peak load that cannot be handled. And this is not only a question of peak or probability, or sometime, in real world situations, the question of economics.

Professor Nehmer asked how resource conflicts will be handled if the system is going to run without a real-time operating system. Professor Kopetz answered in two parts. In the first part he said that the set of processes were restricted to those which the execution time could be determined if they were executed in one processor, considering that interruptions did not occur - this task could be done efficiently off-line. In the second part, he said that their operating system has only one interrupt - the clock interrupt, which determines the frequency and allocates to every task a slot during which the task runs on the processor in an uninterruptible manner, and therefore, since there is no need to consider the interruption of execution tasks by operating system tasks, they can have a reasonable estimate of the time.

An and the second statement is the second of the destrict equivalence is a statement in the second secon
